Fully symmetric pure control: both encodings audited

The pure portion of variant-regression-v1 is terminal. Its finite and geometric encodings come from corrected exporter verification-v8; the same frozen v8 runner solves them. Mixed phi and doubling attempts in the same run remain pending or running and have no verdict in this report.

On p37/seed0/query2, each pure encoding gives the exact same one signed physical relation as the source-block control:

[(5,-1), (21,-1), (23,+1), (24,+1)]

Both native root enumerations report complete. Both independent signed-set/RREF audits pass, with one distinct projective augmented row and rank 1 of 3 columns. The geometric output contains two field roots; one fails the requirement of four distinct allowed Fp factors. Every surviving sign assignment is checked in the actual group. Discarded nonphysical field roots are not counted as useful relations.

The native coefficient check lowers pure total degree from 16 to 8 and the extension-term count from 1,485 to 495 by using all four elementary symmetric coordinates. This is generic permutation symmetry and is a necessary baseline. It cannot be credited to a twist-derived map.

The native summaries and independent audits are retained loose for inspection (../../results/pure-variant-regression/), with the original commands, hashes and logs under runs/variant-regression-v1/. One thread, 8 GiB and the frozen 1,180/1,200 s limits are unchanged. The host does not admit these component durations as performance evidence. No full-rank collection, recovery, matched rho or full GAE price is supplied.
