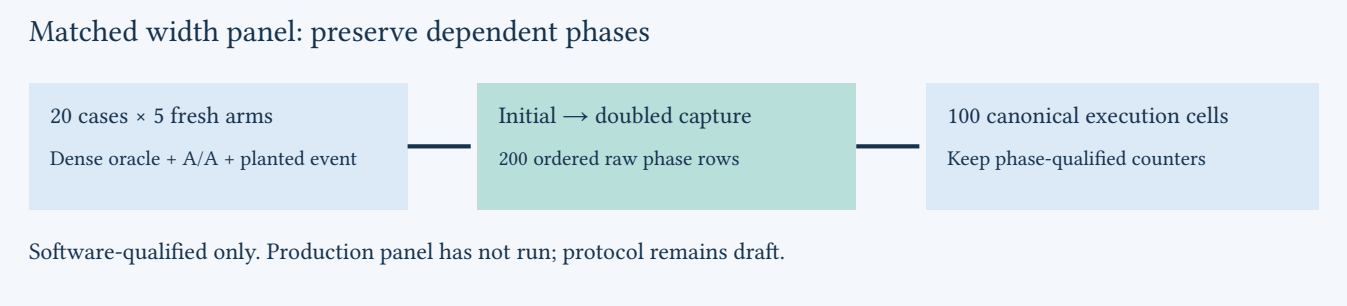
Matched interval-width panel

T-1887 · Prime-field coefficient construction · 2026-11-07

The driver connects scoped field-work counters to old shared width, planned shared width and separate engines. It adds an identical repeat and a planted multiplication. Each arm starts fresh; initial and doubled phases stay separate.



Coefficient oracle. Repeated multiplication by X−1 constructs the dense polynomial independently of the interval/binomial recurrence. Three residue-class streams are extracted in delivery order. Every native arm must match before emitting rows. The reference runs outside capture.

Software qualification. validation01 compiles and passes the disjoint r=41, m=5, cap=2 fixture with all five arms and both phases. Synthetic parser tests reject missing/reordered rows, invalid integer types, bad counters/coefficients and failed controls. The adapter tests qualify 100 canonical cells from 200 synthetic phase rows and reject mismatched receipts. These temporary mock records are not experiment results.

Canonical export. Each execution cell holds initial and doubled metric names. They are dependent stages, not independent replicates. Export requires a frozen protocol, pinned sources/binary/commit, successful producer receipt, raw hash and admission reference. Those checks establish consistency; they do not authenticate an independent scientific verdict.

Current execution status. The full 20-case panel has not run. The protocol passes canonical validation but remains draft: production build binding, runtime preflight and execution admission are missing. The proposed one-attempt ceiling is not reserved funding or submission authority. No cloud job or timing comparison ran.

Failure retained. System Python could not load Draft202012Validator; the existing research venv and pinned canonical tool passed. Native and adapter checks passed. Independent signed verification is pending.

Next construction. Bind and freeze the production comparison before collecting costs. Preserve per-case regressions and separate first-stream setup from rescue work. Add source/coefficient work outside the interval boundary before any total-work conclusion.
