Independent nonmonic division review

Nineteen main declarations, twenty-two producer controls and eight independent controls passed fresh replay. Forty-nine exact named readbacks use standard Lean axioms or none. Eleven module exits were zero. Rust acceptance passed; an actual false equality failed with exit one, and a substituted sorryAx was rejected.

Derived correspondence. Leading inversion comes from the retained modular-exponentiation/Fermat proof, without an assumed inverse witness. Both leading-one and inverse-one shortcuts decode correctly. Top cancellation gives strict remainder descent, quotient conservation and sufficient-fuel success. An independent factorization yields the exact stored canonical word quotient.

Scope retained. Native correspondence is odd-prime n=1 without tables, with canonical operands, nonzero actual leading word and $p < 2^{31}$. The arithmetic theorem's prime-two case does not establish native binary dispatch. Pure inverse recomputation matches values, not native cached operation counts.

Boundary controls. Noncanonical eighteen has inverse one modulo seventeen; canonicality excludes it. The unguarded model returns on empty input with zero leading word, while native code would assert during inversion. Advertised theorems exclude this malformed input; complete panic/admission semantics are not modeled. Largest canonical leading words, mismatched leading parameter and minimal fuel were also checked.

Custody and failures. Published source bytes match the reviewed commit; prior monic/storage familiarity is disclosed. Rust parser support for no-axioms output was corrected. An initial missing-file control was preserved and replaced with an actual false equality. Cached dependencies remain trusted. No Python, scientific execution or repository edits occurred.
